Internal Report ACT-RPT-4100-DI-LMSP01

Abstract—In its classical definition Lambert's problem deals with ballistic arcs, i.e. conic sections. With new propulsion technologies having reached unprecedented maturity levels it is now meaningful to consider other types of solutions to the dynamic of objects in a simple newtonian gravitational field. It is therefore opportune to reconsider Lambert's problem taking into account forced dynamical behaviors. In this work the solution to Lambert's problem is given for a particular class of low-thrust trajectories named exponential sinusoids. The equivalent to Lambert's Theorem is derived, the time of flight curves are parameterized with a suitable variable and some discussion is made on some possible applications.

I. INTRODUCTION

LOW thrust trajectories are becoming increasingly important in the design of space missions. The progress that allowed ion propulsion to become a competitive option for many space missions may be soon be repeated for many other advanced propulsion systems that promise, in a future, to deliver long duration thrust with high specific impulses and high reliability. Most of the methods used to find the optimal trajectories to be followed by spacecrafts equipped with low-thrust capabilities, are based on a transcription of the optimal problem into a Non Linear Programming (NLP) problem and then on the solution of the NLP via numerical techniques. The approach, though successful in the detailed design of trajectories, fails in providing the designers with a tool to efficiently explore a large number of options. With this respect it is clear that the use of analytical methods such as that suggested by Markopoulos [1] could make a difference. In his Ph.D. thesis Petropoulos [2] introduced for the first time a new analytical solution to the problem of low-thrust trajectories. His solution, based on the use of an exponential sinusoid, is based on an inverse dynamical calculation that leads to analytical expressions both for the thrusting history and for the derivative of the polar anomaly, whenever tangential thrust is assumed. His discovery added up to the small list of analytical solutions [3] available for this increasingly important problem. Moreover, his shape based method, inspired many other researchers. De Pascale et al. [4] during their work in the Advanced Concepts Team of the European Space Agency, tried to solve the problem of constraint violations at the trajectory boundaries (likely to happen with the exponential sinusoid) by introducing shapes defined by a larger number of parameters and by using an equinoctial element formulation. Their method is able to satisfy the boundary conditions at the cost of violating the dynamic in a least square sense. In the same direction is the work by Patel et al. [5] where an attempt is made to optimise a large class of shapes given in cartesian coordinates without violating

the dynamic. These last approaches constitute a compromise that allow a search through reasonably large sections of the solution space. When the problem gets complicated, though, also these methods suffer from the "curse of dimensionality" and may result in a rather slow search. Inspired by the recent results obtained [6] in the framework of the ESA research scheme ARIADNA on the case of simple Multiple Gravity Assist problems with powered swing-bys, the idea was born that polynomial complexity of the optimisation problem could be reached also in the low-thrust case, if an equivalent to the Lambert problem solver could be found. The exponential sinusoids found by Petropoulos are a perfect candidate to carry out this task. In a number of works, culminated in the 2004 paper [7], Petropoulos and Longuski seek an application of their new trajectories to the interplanetary transfer problem. Their proposed use of exponential sinusoids is tailored at an algorithmic integration into the pre-existing STOUR software. Though quite successful from a numerical point of view, their work did not set up an appropriate theoretical framework for the generic use of exponential sinusoids. The lack of a generic discussion on the possibility of using these solutions to go from a generic point P_1 to another point P_2 in a given fixed amount of time was particularly evident. It is well known that, in the case of ballistic arcs, this problem, named "Lambert's problem" admits a number of solutions equal to $1 + 2N$, $N = 1, 2, \dots$ as soon as a "short way" or a "long way" gets selected [8]. In what follows we will investigate on what we call the multi-revolution Lambert's problem for exponential sinusoids. When referring to the classical Lambert's problem we will instead explicitly state that we are considering ballistic arcs, i.e. conic sections.

II. PETROPOULOS EXPONENTIAL SINUSOIDS

In this section we briefly review the definition of the exponential sinusoids and we comment upon the use of these trajectories made in the STOUR-LTGA program [7]. Let us start from the equation of motion of a point mass in a Newtonian gravity field under the hypothesis of some added thrust acting on the particle:

$$\begin{cases} \ddot{r} - r\dot{\theta}^2 + \mu/r^2 = F \sin \alpha \\ \ddot{\theta}r + 2\dot{\theta}\dot{r} = F \cos \alpha \end{cases} \quad (1)$$

The idea of Petropoulos is that of trying to see whether an exponential sinusoid defined by the equation:

$$r = k_0 \exp[k_1 \sin(k_2 \theta + \phi)] \quad (2)$$

may be solving the equation of motion 1. It turns out that under the hypothesis of tangential thrust, i.e. $\alpha = \gamma$, the thrust history

Fig. 1. Multirevolution Lambert's problem: geometry definition

and the polar angle history are uniquely determined for each exponential sinusoid by some analytical expressions. These expressions link $\dot{\theta}^2$ and $a = F/(\mu/r^2)$ to the four parameters $[k_0, k_1, k_2, \phi]$ defining each exponential sinusoid. They were derived by Petropoulos [2] and are reported here for the sake of completeness:

$$\dot{\theta}^2 = \left(\frac{\mu}{r^3}\right) \frac{1}{\tan^2 \gamma + k_1 k_2^2 s + 1} \quad (3)$$

$$a = \frac{\tan \gamma}{2 \cos \gamma} \left[\frac{1}{\tan^2 \gamma + k_1 k_2^2 s + 1} - \frac{k_2^2 (1 - 2k_1 s)}{(\tan^2 \gamma + k_1 k_2^2 s + 1)^2} \right] \quad (4)$$

where the flight path angle is defined by:

$$\tan \gamma = k_1 k_2 \cos(k_2 \theta + \phi) \quad (5)$$

and $s = \sin(k_2 \theta + \phi)$. Some analysis reveals that these expression are meaningful whenever $k_1 k_2^2 > 1$ revealing that the exponential sinusoid shape may be followed by using only a tangential thrust. In the original use made of these new trajectories to locate interplanetary transfers, the velocity at departure is considered to be known which, in turns, allow reduce the definition of the exponential spiral to one free parameter which is chosen to be k_2 . This parameter is then located, with a somewhat complicated procedure, to target the following planet. The resulting algorithm is, according to Petropoulos et Longuski, able to efficiently locate interesting near-optimal solutions, but it makes use of an enumerative search to locate the "good" trajectories.

III. ANOTHER POINT OF VIEW

In this section we introduce the multi-revolution Lambert's problem for exponential sinusoids. Given r_1, r_2 (see Figure 1) and the transfer angle ψ we want to find all the exponential sinusoids, defined by eq.(2), that link the two positions in a given transfer time t , allowing for multiple revolutions. We start by reducing the search space assuming k_2 fixed. We therefore study the problem for all the exponential sinusoids defined by only the three free parameters k_0, k_1 and ϕ . Without loss of generality we fix our polar coordinate system so that $\theta_1 = 0$. We then write eq.(5) in correspondence to the first point:

$$\tan \gamma_1 = k_1 k_2 \cos \phi \quad (6)$$

It is convenient to use γ_1 i.e. the flight path angle at r_1 , instead of ϕ to parameterize the exponential sinusoids. We are only interested in those trajectories that actually do pass by the points r_1 and r_2 . We enforce this by writing the relations:

$$\begin{cases} r_1 = k_0 \exp[k_1 \sin \phi] \\ r_2 = k_0 \exp[k_1 \sin(k_2 \bar{\theta} + \phi)] \end{cases}$$

where $\bar{\theta} = \psi + 2\pi N$ and $N = 0, 1, 2, \dots$, accounts for the possibility of having more than one revolution. By dividing the two equations and taking the logarithm we may derive first the expression:

$$\frac{k_1}{|k_1|} \sqrt{k_1^2 - \frac{\tan^2 \gamma}{k_2^2}} = \frac{\ln \frac{r_1}{r_2} + \frac{\tan \gamma_1}{k_2} \sin k_2 \bar{\theta}}{1 - \cos k_2 \bar{\theta}}$$

that tells us what the sign of k_1 has to be, and then the following:

$$k_1^2 = \left(\frac{\log \frac{r_1}{r_2} + \frac{\tan \gamma_1}{k_2} \sin k_2 \bar{\theta}}{1 - \cos k_2 \bar{\theta}} \right)^2 + \frac{\tan^2 \gamma_1}{k_2^2} \quad (7)$$

We also have, trivially:

$$\phi = \arccos \left(\frac{\tan \gamma_1}{k_1 k_2} \right) \quad (8)$$

and,

$$k_0 = \frac{r_1}{\exp(k_1 \sin \phi)} \quad (9)$$

We note that there is no loss of information in considering the angle ϕ in the first two quadrants as the consideration of other possibility would simply return the very same exponential sinusoid. Given the geometry of the problem, i.e. given r_1, r_2 and ψ and given the number of revolutions required, i.e. given N we are now able to say that $\forall k_2$ there exist a class $\mathcal{S}_{k_2}[r_1, r_2, \psi, N]$ of exponential sinusoids passing through r_1 and r_2 and conveniently parameterized by the sole free parameter γ_1 . The analogy with the theoretical developments that are faced when solving Lambert's problem for ballistic arcs is worth to be noted. Also in that case (see Battin [8]) we arrive at showing that there exist a whole family of ellipses/hyperbolae connecting two given points and we parameterize them conveniently either via the semi-major axis or, even better, by some other alternative variable.

IV. INTRODUCING THE DYNAMIC FEASIBILITY

All that we did in the previous section is only geometrical and there is no information we introduced on the dynamic. We now ask ourselves which of the exponential sinusoids belonging to $\mathcal{S}_{k_2}[r_1, r_2, \psi, N]$ are actually feasible trajectories for spacecrafts. We call an exponential sinusoid feasible whenever it is possible to find a tangential thrust history able to induce that trajectory. Given in these terms the answer is already contained in Petropoulos Ph.D. dissertation, the condition is $k_1 k_2^2 < 1$. We may rewrite this condition exploiting eq.(7):

$$\left(\frac{k_2^2 \log \frac{r_1}{r_2} + k_2 \frac{\tan \gamma_1}{k_2} \sin k_2 \bar{\theta}}{1 - \cos k_2 \bar{\theta}} \right)^2 + k_2^2 \tan^2 \gamma_1 < 1 \quad (10)$$

Fig. 2. The exponential sinusoids family $\mathcal{S}_{1/4}[1, 1.5, \pi/6, 1]$ Fig. 3. Feasible exponential sinusoids in the classes $\mathcal{S}_{1/2}[1, 5, \pi/2, 0]$ (left) and $\mathcal{S}_{1/4}[1, 5, \pi/2, 1]$ (right)

Some algebra reveals that this is a quadratic equation in $\tan \gamma_1$, an equation that allows us to define analytically the interval of γ_1 for which the exponential sinusoids in \mathcal{S}_{k_2} are feasible. We find:

$$\tan \gamma_{1m,M} = \frac{k_2}{2} \left[-\log \frac{r_1}{r_2} \cot \frac{k_2 \bar{\theta}}{2} \pm \sqrt{\Delta} \right] \quad (11)$$

where:

$$\Delta = \frac{2(1 - \cos k_2 \bar{\theta})}{k_2^4} - \log^2 \frac{r_1}{r_2}$$

Trivially if $\Delta < 0$ no exponential sinusoid belonging to \mathcal{S}_{k_2} is a feasible trajectory.

As an example of feasible exponential sinusoids we have plotted some examples in Figure 3. In particular we have considered the family $\mathcal{S}_{1/2}[1, 5, \pi/2, 0]$ and the family $\mathcal{S}_{1/4}[1, 5, \pi/2, 1]$. All the trajectories shown may be followed by a spacecraft with unlimited thrusting capabilities that thrusts tangentially to the trajectory. The thrust history, as well as the anomaly history, are uniquely determined for each chosen trajectory by eq.(3) and eq.(4).

Fig. 4. Time-of-flight versus the flight-path angle for the class $\mathcal{S}_{1/12}[1, 1.5, \pi/2, N]$

V. TIME OF FLIGHT

If, on one hand, there is a close relation between the developments presented in the previous section and those introduced in the classical Lambert's problem for ballistic arcs, on the other hand the differences are also noteworthy. When ellipses are considered to join the starting and ending position, a pure geometrical approach leads to define a minimum energy ellipse that introduces a limit on the semi-major axis of the possible solution. For exponential sinusoids such a limit may be introduced on γ_1 (eq.(11)) only after dynamic is taken into consideration. In the original problem the time-of-flight equation could be conveniently expressed analytically as a function of the parameter chosen to describe the family of geometrically feasible ellipses. In the case of exponential sinusoids this is not possible and the time-of-flight has to be evaluated by integrating by numerical quadrature the expression given by eq.(3). Fortunately the chosen parametrization for the exponential sinusoids is a good one and all the time of flight curves are monotone in γ_1 , as shown for a particular case in Figure 4. A very simple numerical method such as Regula Falsi may therefore be efficiently used to detect the solution of the Lambert's problem for a particular class of exponential sinusoids by finding the intersection, if existing, between the time-of-flight curve and an horizontal line. We observe that the asymptotic behavior of these time-of-flight curves is quite different from the one we know from the case of ballistic arcs and does not allow to conclude that the problem always has a solution. Also, their being monotone allow us to skip the definition of left branch and right branch necessary in the multi-revolution Lambert's problem for ballistic arcs.

We may now state, for the exponential sinusoids belonging to a given class \mathcal{S}_{k_2} , the following equivalent to Lambert's Theorem:

$$t_2 - t_1 = F \left(\tan \gamma_1, r_1, \frac{r_1}{r_2}, \bar{\theta} \right)$$

and we may add that F is a single-valued monotone function of γ_1 . In this sense Lambert's problem for exponential sinu-

soids poses less mathematical challenges than its equivalent for ballistic arcs.

VI. TERMINAL VELOCITY VECTORS

It is well known that in the classic ballistic transfer problem the terminal velocity vectors are closely related. An elegant way of expressing such a relation has been found by Thore Godal [9] who introduced a skew axis system in which the analytical relationship assumes a noteworthy expression. In the case of exponential sinusoids it is also possible to derive a similar relation. Let us write the expression for the flight-path angle in the final point:

$$\tan \gamma_2 = k_1 k_2 \cos(k_2 \bar{\theta} + \phi)$$

if we now substitute into this expression eq.(6) and eq.(7), after some manipulations it is possible to show that for each sinusoid belonging to a given class \mathcal{S}_{k_2} the following relation is valid:

$$\tan \gamma_2 = -\tan \gamma_1 - k_2 \log \frac{r_1}{r_2} \cot \frac{k_2 \bar{\theta}}{2}$$

We have established a relation between the terminal velocity vectors, a relation that may be written in an even more compact form if we take into account eq.(11):

$$\tan \gamma_2 = \tan \gamma_{1_m} + \tan \gamma_{1_M} - \tan \gamma_1 \quad (12)$$

This last expression is quite unexpected. It establishes an elegant link between a pure geometrical relation such as that between the terminal flight path angles of all the exponential sinusoids linking two points and two quantities, γ_{1_m} and γ_{1_M} whose definition is intrinsically linked to the dynamic of a body in a newtonian gravitational field.

VII. A POSSIBLE APPLICATION TO ORBITAL TRANSFERS

Let us consider the design of a multiple gravity assist mission. The goal is to rendezvous with a given planet maximizing the final mass of the spacecraft at the rendezvous. If only ballistic arcs are allowed to connect the various planets then our decision vector will be $\mathbf{x} = \{t_s, \Delta t_i\}$ i.e. the departure date t_s , the various arc lengths Δt_i . Once these numbers are given, and whenever multiple revolutions are not accounted for, there exist only one possible ballistic trajectory as a consequence of the classical Lambert's theorem. This trajectory may be feasible or unfeasible depending on other mission constraints such as maximum departure velocity (relative to the Earth), minimum pericentrum for the various planet fly-by and others. The problem may be complicated by allowing for multiple revolutions and deep space manoeuvres, but in this simple form it has been shown to have a polynomial complexity whenever a particular pruning technique [6] is used.

When exponential sinusoids are substituted to ballistic arcs, we must face the problem of choosing the shape parameter k_2 for each arc. The simplest case of an interplanetary transfer between two bodies will therefore have a three dimensional decision vector $\mathbf{x} = \{t_s, \Delta t_1, k_2\}$. Let us for example take the Earth-Mars case and let us use JPL ephemerides DE405 to evaluate the positions of the planets. Once the decision vector

Fig. 5. Earth-Mars optimum in the trajectory class of the exponential spirals $N = 0$. Units are all non-dimensional

is known we may evaluate the position of the Earth when the spacecraft is launched and the position of Mars at rendezvous. We therefore know $r_1, r_2, \psi, k_2, \Delta t_1$ and we may try to locate that unique exponential sinusoid in the class $\mathcal{S}_{k_2}[r_1, r_2, \psi, N]$ that has Δt_1 as time of flight and therefore to associate a “fitness” to the proposed solution. This opens the possibility of considering a number of global optimisation techniques to find the best possible low-thrust trajectory in the restricted class of the exponential sinusoids.

As a preliminary example we here use the Differential Evolution technique (see Storn [10]) to try locating the global optimum of the following function:

$$J = \int_0^{\bar{\theta}} \frac{|a|}{\bar{\theta}} d\theta$$

in the space of all the possible exponential sinusoids transferring from Earth to Mars. It is possible to show that this problem is equivalent to the problem of minimizing the ratio $\frac{m_p}{m_0}$ between the mass of propellant used during the thrust arc and the remaining spacecraft mass m_0 . We select the following bounds for the decision variables (implemented via step penalty functions): $t_0 \in [2000, 5000]$ MJD, $\Delta t \in [200, 2000]$ days and $k_2^1 \in [.01, 1]$. We then search the global optimum in the case of $N = 0$, $N = 1$ and $N = 2$. Figure 5 visualize the trajectory found in the case $N = 0$ and the non dimensional thrust history in this case. The results are summarized in Table I. The algorithm was run for many times and returned the

| N | t_0 (MJD) | Δt (Days) | k_2 |
|---|-------------|-------------------|-------|
| 0 | 4115 | 206 | .928 |
| 1 | 2034 | 532 | .523 |
| 2 | 2021 | 1012 | .2361 |

TABLE I
GLOBAL OPTIMA FOR THE EARTH-MARS CASE WITHOUT C3
CONSTRAINTS

global optimum roughly 60% of the times. The trajectories

found are optimal in the class of the exponential sinusoids, it remains to be investigated how rich this class is in terms of its ability of representing possible real solutions. In this particular case, as no constraints were put on the departure and arrival C3, the optimal solution in the wider class of all the possible solutions to eq.(1) is a ballistic arc, i.e. $J=0$ and it is not represented by the exponential spirals.

More general cases may also be optimised, i.e. considering gravity assists, in which case the decision vector would be $\mathbf{x} = \{t_s, \Delta t_i, k_2^i\}$ and the optimisation could take into account pruning techniques such as those introduced by Myatt et al. [6] to try to efficiently solve the problem.

VIII. CONCLUSIONS

The multi-revolution Lambert's problem has been introduced for the exponential sinusoids and solved. Given the radius ratio the transfer angle and the number of revolutions it has been shown how $\forall k_2$ there exist a family of exponential sinusoids passing through the desired points and conveniently parameterized by the flight path angle at the starting point γ_1 . The functional relationship between γ_1 and the time of flight is monotone and its domain is defined by the dynamical feasibility of the resulting trajectories. An example of the use of these results in the search for optimal interplanetary trajectories is given and some future work is suggested.
